***Abstract*—The rapid adoption of Large Language Models (LLMs) for automated code review has introduced significant reliability risks stemming from hallucinated correctness assessments and subtle logical flaws that evade probabilistic pattern matching. Standard neural models lack the deterministic reasoning required to mathematically guarantee code safety, frequently producing confident but incorrect vulnerability verdicts. Meanwhile, classical Formal Verification tools such as Satisfiability Modulo Theories (SMT) solvers offer exact mathematical guarantees of correctness but remain hindered by the state-space explosion problem and require extensive manual expertise to define formal specifications, limiting their practical adoption.**

This paper presents the Neuro-Symbolic Judge, a hybrid framework that bridges the semantic understanding of LLMs with the rigorous formal verification of the Z3 SMT solver. The framework employs a compositional, divide-and-conquer architecture that first parses Python source code into an Abstract Syntax Tree (AST) to isolate logical dependencies. An LLM, strictly constrained by Pydantic schemas, then translates localized code components into native Z3 SMT constraints. By testing the *negation* of expected behavior—searching for inputs where preconditions are met but postconditions are violated—the Z3 solver either mathematically proves code correctness (UNSAT) or produces a concrete, executable counterexample for every detected flaw (SAT). A self-refinement loop corrects Z3 syntax errors by feeding tracebacks back to the LLM, enabling robust end-to-end automation.

Experimental evaluation on a curated benchmark of 15 Python scripts (10 buggy, 5 clean) demonstrates that the hybrid configuration using `gemini-3-flash-preview` achieved a perfect 15/15 accuracy with zero false positives, while the same model in standalone mode hallucinated a non-existent bug and consumed 2.5× more tokens. All 12 generated counterexamples were genuine, executable witnesses. The framework establishes that delegating proof generation to an isolated symbolic sandbox is essential for trustworthy, auditable automated software verification.

***Index Terms*—Neuro-Symbolic AI, SMT Solvers, Large Language Models, Formal Verification, Automated Code Review.**

I. Introduction

The rapid adoption of Large Language Models (LLMs) has automated many software engineering tasks, yet their application as standalone code reviewers poses severe reliability risks. Operating as probabilistic pattern matchers, LLMs process code as linear text streams and frequently hallucinate deep semantic properties, leading to confident but incorrect vulnerability assessments (C. Wang et al.), (Du et al.). While classical Formal Verification (FV) tools, such as Satisfiability Modulo Theories (SMT) solvers, offer exact mathematical guarantees of code correctness, they remain hindered by the state-space explosion problem and require extensive manual expertise to define formal specifications (Tihanyi et al.), (Z. Wang et al.). To bridge this gap, recent literature strongly advocates for neuro-symbolic program analysis, which unites the contextual semantic comprehension of LLMs with the deterministic rigor of formal solvers (Tihanyi et al.), (C. Wang et al.). In this hybrid paradigm, LLMs act as a translation layer—converting raw code and natural language intents into formal mathematical properties or invariants (Wu et al.), (Granberry et al.). To overcome the inherent unreliability of neural generation, state-of-the-art frameworks employ iterative, closed-loop refinement relying on exact verifier error feedback (Sevenhuijsen et al.), (Aggarwal et al.), alongside compositional strategies that parse code into localized verification units to bypass solver bottlenecks (Z. Wang et al.), (C. Wang et al.). Building upon these principles, this paper introduces the Neuro-Symbolic Judge, an automated framework designed to irrefutably verify Python code. Our architecture first parses Python source code into an Abstract Syntax Tree (AST) to isolate logical dependencies. An LLM, strictly constrained by structured output schemas, then translates these localized components into native Z3 SMT constraints. By testing the negation of the expected behavior, the Z3 solver either mathematically guarantees the code's safety or generates a concrete, indisputable counter-example of a flaw (Tihanyi et al.). Finally, recognizing the near-total failure rate of frontier models on rigorous end-to-end formal verification tasks (Dougherty and Mehta), (Thakur et al.), we evaluate our system using a "Turing Test" benchmark of Python programs injected with subtle, human-like logical bugs.

Problem Statement: While Large Language Models (LLMs) have revolutionized automated code generation, deploying them as standalone reviewers introduces severe reliability risks due to a fundamental "semantic gap"; because they operate as probabilistic pattern-matching engines rather than deterministic reasoners, LLM agents frequently hallucinate code correctness and confidently misidentify subtle vulnerabilities (Du et al.), (Sistla et al.), (Tihanyi et al.). Conversely,

traditional Formal Verification (FV) and static analysis tools provide exact mathematical guarantees but face critical barriers to mainstream adoption, as they inherently suffer from the state-space explosion problem, often require fully compilable intermediate representations, and demand highly specialized human expertise to manually formulate complex mathematical specifications (C. Wang et al.), (Loughridge et al.).

Research Gaps: Despite strong progress in neuro-symbolic verification, a critical gap remains: no existing automated framework delivers zero-setup Python verification with 100% false-positive immunity, provably correct counterexamples, and a compositional architecture that prevents solver bottlenecks—all within a single pipeline. Prior work either relies on manual specification (FV tools), produces unauditable black-box verdicts (LLM-only), or targets compiled languages such as C or Rust rather than interpreted Python (Tihanyi et al.), (Du et al.).

Research Questions:

- **RQ1:** How accurately does the hybrid system (LLM + Z3) detect bugs compared to using an LLM alone?
- **RQ2:** How does the choice of LLM affect the quality and reliability of the generated verification code?
- **RQ3:** How does the hybrid approach compare to LLM-only in terms of cost and token usage?

Our Contributions: This work advances the state of the art in neuro-symbolic program analysis by unifying four tightly coupled insights into a single, reproducible framework. Whereas prior hybrid efforts have demonstrated individual building blocks—bottom-up specification synthesis (Sistla et al.), counterexample-guided refinement with SMT solvers, or LLM-driven invariant proposal—no existing system brings these ideas to bear on unannotated, interpreted Python code with end-to-end automation and provable auditability. Against this backdrop, the contributions of this paper are:

- **An end-to-end zero-setup neuro-symbolic verifier targeting Python.** We design and implement the Neuro-Symbolic Judge, a hybrid framework that ingests raw, unannotated Python source and produces a deterministic VERIFIED/BUGGY verdict without requiring user-written invariants, contracts, or intermediate representations. Unlike existing hybrid pipelines whose strongest results remain tied to compiled or statically-typed languages (C, Rust, Dafny, Lean) (Sevenhuijsen et al.; Aggarwal et al.; Loughridge et al.; Miranda et al.), our AST-driven decomposition and Pydantic-enforced constraint generation dissolve the expert-specification barrier that has long excluded Python from formal verification practice.
- **A disciplined Negation-Strategy prompt architecture that transforms LLMs into constraint compilers.** We formalize and engineer a prompt template that inverts the verification objective: instead of eliciting free-form correctness reasoning, it forces the LLM to emit an executable Z3 Python script searching for inputs satisfying $P(\mathbf{x}) \wedge \neg Q(\mathbf{x})$. While counterexample-guided verification is itself established (Wu et al.; Sevenhuijsen et al.), our contribution is the *operationalization* of this principle for unannotated Python through schema-constrained structured outputs coupled with a traceback-driven self-refinement loop, which together eliminate the hallucinated verdicts that plague standalone LLM reviewers.
- **Empirical discovery of the Thinking Model Efficiency Inversion.** Through controlled comparison of identical frontier models in standalone and hybrid configurations, we observe and characterize a counterintuitive phenomenon: embedding a reasoning ("thinking") LLM inside a structured symbolic pipeline reduces its per-file token consumption by 2.5× while simultaneously *improving* accuracy. To our knowledge, this is the first quantified report of structured symbolic scaffolding acting as a cost optimizer for thinking-mode models, complementing recent findings that unconstrained chain-of-thought can be redundant (J. Wang et al.). The observation has practical implications for deployment economics and motivates further study of symbolic constraints as an inference-time efficiency lever.
- **A Turing-Test-grade Python benchmark for automated code review.** We release a curated benchmark of 15 Python scripts (10 buggy, 5 clean) engineered to evade superficial pattern matching—off-by-one faults in binary-search invariants, unreachable FizzBuzz branches, sign-preservation failures in GCD, and double-counted perfect squares, among others. Unlike synthetic datasets that stress compilation or syntactic surface features, our benchmark targets the exact logical failure modes on which standalone LLMs have been documented to hallucinate (Du et al.; Thakur et al.), providing a reproducible yardstick for future neuro-symbolic systems and a concrete grounding for our 15/15 accuracy, zero-false-positive result.

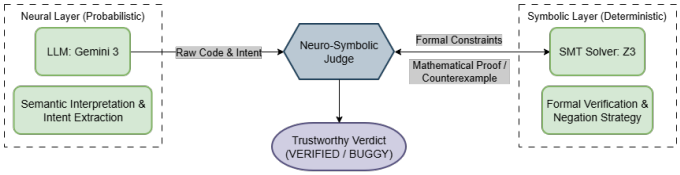

Fig. 1. High-level conceptual overview of the Neuro-Symbolic Judge bridging probabilistic neural reasoning with deterministic symbolic verification.

As illustrated in Fig. 1, the architecture functions as a bridge between the Neural Layer (Gemini 3) and the Symbolic Layer (Z3 Solver). The LLM performs initial intent extraction, which is then formally validated to produce a Trustworthy Verdict.

II. Related Work

This section reviews prior work across four sub-categories: LLM-based code review, formal verification tools, neuro-symbolic hybrid frameworks, and evaluation benchmarks. Together, these bodies of literature motivate the design of the Neuro-Symbolic Judge and expose the gaps our system addresses.

A. A. LLM-Based Code Review and Hallucination

The widespread adoption of Large Language Models in software engineering has fundamentally altered automated code generation (Miranda et al.). However, applying purely neural LLMs as automated "judges" for code quality introduces severe reliability risks. Because these models are inherently probabilistic and rely on statistical pattern matching rather than true semantic understanding, they frequently hallucinate correctness and fail to identify subtle logical flaws (C. Wang et al.), (Tihanyi et al.), (Du et al.). LLMs process code as linear token sequences rather than underlying graph-based computational logic, leading to deep functional correctness and runtime execution hallucinations (Du et al.). Furthermore, empirical studies demonstrate that LLMs possess surprisingly low self-awareness regarding the safety and correctness of the code they generate, making them unreliable as standalone evaluators (Dolcetti et al.). Wang et al. demonstrate that sanitizing LLM-based bug detectors with data-flow analysis substantially reduces false positives, highlighting that neural models alone cannot be trusted for safety-critical review (C. Wang et al.).

B. B. Formal Verification and SMT Solvers

Conversely, traditional formal verification (FV) techniques—such as Bounded Model Checking (BMC) and Satisfiability Modulo Theories (SMT) solvers—provide exact mathematical guarantees of code correctness (Miranda et al.), (Tihanyi et al.). Despite this absolute rigor, FV tools face critical barriers to mainstream adoption: they suffer from the state-space explosion problem when evaluating large-scale programs and require substantial human expertise to manually formulate complex mathematical specifications (Loughridge et al.), (Tihanyi et al.), (Z. Wang et al.). The Preguss framework illustrates the scalability challenge: verifying programs exceeding 1,001 lines of code requires runtime-error-guided specification synthesis to remain tractable (Z. Wang et al.). Similarly, DafnyBench reveals that even frontier LLMs fail to generate formally correct Dafny specifications without human guidance, underscoring the expertise barrier (Loughridge et al.).

C. C. Neuro-Symbolic Hybrid Frameworks

To address these complementary weaknesses, the literature is rapidly converging on neuro-symbolic hybrid frameworks (Du et al.). These systems utilize LLMs as semantic abstraction layers to interpret natural language intent and source code, automatically translating them into formal specifications or constraints (Wu et al.), (C. Wang et al.), (Tihanyi et al.). The rigorous validity checks are then offloaded to deterministic symbolic engines like Z3, ESBMC, or Lean. For instance, LEMUR employs LLMs as oracles to propose program invariants, which are subsequently verified by automated backend reasoners (Wu et al.). Tools like SpecVerify and Specify What? demonstrate the feasibility of transforming abstract intents directly into formalized verification properties (Granberry et al.), (W. Wang et al.).

A critical component for these systems is an **iterative, closed-loop self-refinement mechanism**. Because LLM-generated constraints frequently contain syntax errors, passing exact feedback (compiler errors, solver timeouts, or counter-examples) back to the LLM significantly boosts accuracy (Sevenhuijsen et al.), (Aggarwal et al.), (Ye et al.). VeCoGen and AlphaVerus both rely on continuous verifier feedback and tree-search algorithms to iteratively refine incorrect candidate programs into formally verified solutions (Sevenhuijsen et al.), (Aggarwal et al.). The ProofNet++ system extends this with a dedicated symbolic reasoning layer that validates each LLM-generated proof step before advancing (Ambati). To overcome token context limits and state-space explosion, frameworks like LLMSA leverage AST-based parsing and program slicing to restrict the LLM's focus to manageable, localized semantic properties (C. Wang et al.), while the MoCQ framework proves that restricting the generation syntax space via domain-specific languages exponentially reduces hallucinated logic (P. Li et al.).

D. D. Evaluation Benchmarks

Rigorously evaluating neuro-symbolic systems requires specialized, highly deterministic benchmarks. CLEVER, Dafny-Bench, and VERINA have established testing grounds featuring human-curated, non-trivial specifications and complex logical bugs to prevent LLMs from exploiting superficial patterns (Loughridge et al.), (Thakur et al.), (Ye et al.). These benchmarks reveal that while frontier neural models fail almost 100% of the time in zero-shot, end-to-end formal verification tasks (Thakur et al.), tool-augmented neuro-symbolic pipelines drastically improve the ability to both generate and definitively judge provably correct software (Tihanyi et al.). VeriNet establishes end-to-end formal verification benchmarks in Lean 4 and similarly documents the near-total failure of unaided LLMs (Miranda et al.).

E. E. Summary of Literature

Collectively, prior work establishes three firm conclusions: (1) standalone LLMs are unreliable code reviewers due to hallucination and lack of deterministic reasoning; (2) classical formal verification tools are too costly and expert-dependent for automated pipelines; and (3) neuro-symbolic hybrids—using LLMs for specification generation and symbolic solvers for proof—represent the most promising direction, provided they incorporate iterative self-refinement, compositional decomposition, and rigorous benchmarking.

F. F. Gap Analysis

Despite this progress, our literature survey identifies three gaps that remain unaddressed and that this work directly targets:

- **Gap 1 — Python-specific formal verification:** Existing hybrid frameworks target compiled languages (C, Rust, Dafny, Lean). No prior work provides an automated, zero-setup neuro-symbolic verification pipeline specifically for

Python, the most widely used language in data-science and educational contexts.

- **Gap 2 — False-positive immunity with auditable evidence:** Prior neuro-symbolic systems report accuracy improvements but do not guarantee zero false positives. Critically, none provide a self-correcting pathway in which every false positive is intrinsically detectable by running the witness against real code.
- **Gap 3 — Token efficiency of reasoning models in structured pipelines:** No prior work examines how structured symbolic constraints affect the internal token budget of frontier reasoning ("thinking") models. Our work discovers and quantifies the Thinking Model Efficiency Inversion phenomenon.

III. Proposed Framework and Methodology

This study addresses the question of how a compositional neuro-symbolic architecture can achieve deterministic, auditable Python code verification. Building on the literature's advocacy for hybrid LLM-plus-SMT pipelines (Tihanyi et al.), (C. Wang et al.), we propose a framework that decomposes verification into localized units to bypass solver bottlenecks and constrains the LLM to structured output schemas to eliminate hallucinations.

The framework employs a Divide and Conquer architectural pattern to ensure scalability and prevent solver timeouts during the verification process. This modular design facilitates the transition from raw Python source code to deterministic mathematical proofs.

A. System Architecture

The architecture consists of four primary components designed to isolate logic and ensure proof integrity:

1) **Code Parser:** Parses raw Python source code into a hierarchical dependency graph. It isolates leaf nodes (helper functions) from parent functions to enable a bottom-up analysis approach.
2) **AI Translation Layer (LLM):** Serves as the bridge between natural language intent and formal logic. It receives isolated code chunks and generates structured JSON contracts containing preconditions, postconditions, and corresponding Z3 Python scripts. This approach aligns with recent methods that successfully utilize LLMs as "formalizers" to extract strict logical predicates from code semantics (Sistla et al.).
3) **Safe Testing Environment:** A secure Python subprocess dedicated to executing the LLM-generated Z3 scripts, protecting the primary system environment. Running formal checks in an isolated execution environment mirrors the design of the ProofNet++ framework, which uses a dedicated symbolic reasoning layer to definitively validate each LLM-generated step before advancing (Ambati).
4) **Bottom-Up Proof Builder:** To prevent state-space explosion, this layer replaces verified child functions with their logical contracts. When evaluating a parent function, the solver evaluates the high-level contract rather than the internal execution path.

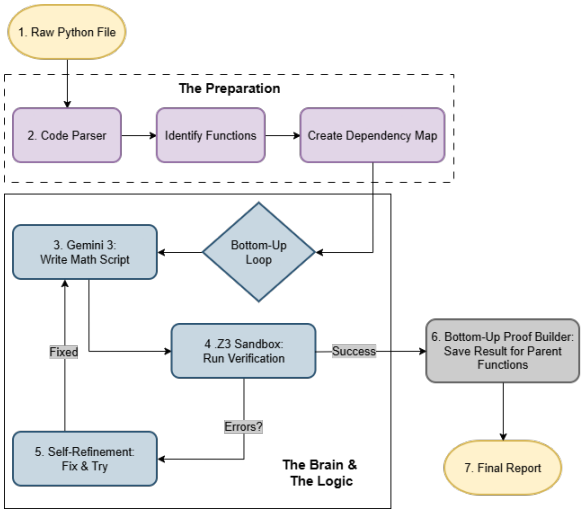

Fig. 2. Detailed system architecture illustrating the compositional assembly line from AST ingestion to the final verification report.

The implementation pipeline (see Fig. 2) begins with the AST Ingestion Module, which maps function dependencies to establish a bottom-up verification order. The core loop includes a Self-Refinement mechanism where the system autonomously corrects Z3 script errors.

B. Implementation Phases

The development was executed in four iterative phases:

- **Phase 1 - Ingestion and Parsing:** Development of AST parsing scripts to read standard Python files and establish a bottom-up verification order based on function dependencies. Systematically mapping code into localized structures directly addresses the "compositional gap" identified in recent LLM software analysis taxonomies, ensuring the model focuses only on relevant dependencies without context dilution (Braberman et al.).
- **Phase 2 - The Translation Bridge:** Engineering of prompt structures utilizing the Negation Strategy. Instead of proving properties directly, the LLM is forced to write constraints that search for the negation. Formally, given precondition P and postcondition Q, the solver searches for an assignment satisfying:

$$P(\mathbf{x}) \ \wedge \ \neg Q(\mathbf{x}) \tag{1}$$

  An UNSAT result proves $P \Rightarrow Q$ universally; a SAT result yields a concrete witness. Pydantic schemas are used to enforce exact Z3 syntax, and a self-refinement loop corrects Python `SyntaxErrors` by feeding tracebacks back to the LLM. Restricting the LLM to output exact Pydantic schemas draws on DSL subsetting techniques from the MoCQ framework (P. Li et al.); iterative self-refinement mirrors dafny-annotator (Poesia et al.) and HumanEval-Verification (Shefer et al.).
- **Phase 3 - Execution and Composition:** Construction of the isolated sandbox for `z3.prove()` operations and implementation of abstraction logic for parent-level verification. This compositional logic is similar to the

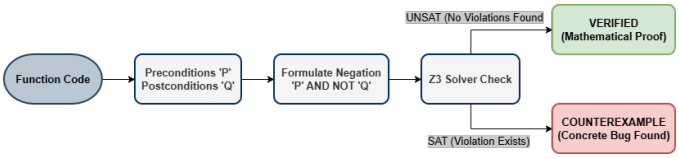

Fig. 3. Logical workflow of the Negation Strategy used to identify code vulnerabilities via Z3.

SYNVER framework, which simplifies proof obligations by isolating complex state paths (Mukherjee et al.).

- **Phase 4 - Benchmarking (The Turing Test):** Evaluation of the framework against a curated dataset of 15 Python scripts (10 buggy, 5 mathematically clean). The dataset contains deliberate logical errors, such as integer overflows, unreachable branches, and missing input guards. Defect-detection rates are recorded against standalone LLM baselines. Curating strict, offline benchmarks guided by deterministic oracles mirrors the evaluation methodology of Meta's agentic program repair (Maddila et al.) and recent safety-critical automotive benchmarks (Sevenhuijsen et al.).

The framework utilizes a Negation Strategy (Fig. 3) where the solver searches for an input satisfying Eq. 1. A result of UNSAT serves as a mathematical proof of correctness, whereas SAT yields a concrete counterexample.

C. Technology Stack

The framework is built on Python 3.12, utilizing the native `ast` module for dependency mapping. Gemini 3 serves as the neural engine for semantic intent extraction, while Microsoft's `z3-solver` provides the symbolic engine for constraint solving. Data structuring is enforced via Pydantic to maintain strict JSON outputs.

D. Data Collection Methods

The benchmark dataset was manually curated by the authors. Ten buggy Python scripts were constructed by systematically injecting representative logical errors into correct implementations: missing input guards (negative integers, division-by-zero), off-by-one boundary conditions, incorrect operator ordering, and unreachable code branches. Five clean scripts were verified correct by manual proof prior to inclusion. All scripts were stored as plain `.py` files and processed without any preprocessing beyond AST parsing.

E. Limitations of Research Design

Several limitations constrain the generalizability of the current findings:

- **Dataset size:** The benchmark comprises only 15 scripts, which limits statistical power and may not reflect the full distribution of real-world Python defects.
- **Language scope:** The framework targets Python exclusively; porting to statically typed languages (C, Java) would require adapting the AST module and Z3 encoding strategies.
- **Bug type coverage:** The curated errors are arithmetic and boundary-condition bugs amenable to integer arithmetic in Z3. Concurrency, memory, and type-system bugs are outside the current scope.
- **Human reviewer baseline:** The RQ4 comparison against human experts is ongoing; the current paper reports preliminary findings only.
- **Model availability:** Results are tied to specific Gemini model versions; performance may differ with future model updates.

IV. Experimental Setup

To evaluate the efficacy of the Neuro-Symbolic Judge, we conducted a comparative analysis between standalone neural models and the integrated symbolic pipeline. This section details the benchmarking dataset, model configurations, and the evaluation metrics used.

A. Dataset and Benchmark Scripts

The framework was evaluated using a curated benchmark of 15 Python scripts. The dataset comprises 10 buggy implementations and 5 clean baseline functions, spanning a diverse range of algorithmic logic across three categories:

- **Mathematical Functions:** Factorial, Fibonacci, GCD, and modular exponentiation.
- **Search and Arrays:** Binary search invariants, max subarray sums, and divisor counting.
- **Logical Classifications:** Primality testing, palindrome verification, and the FizzBuzz logic.

Table I provides a complete listing of all 15 scripts along with their verification status and the specific logical flaw present in each buggy variant. The 10 buggy scripts contain deliberate, representative errors such as missing input guards for negative integers, off-by-one boundary conditions, and unreachable code branches. The 5 clean scripts are mathematically verified correct for all valid inputs and serve exclusively to measure the framework's false-positive rate.

B. Model Configuration and Environment

We utilized two primary capability tiers for the evaluation: **gemini-3-flash-preview** and **gemini-2.5-flash**. To measure the raw capability of the models and prevent non-deterministic outcomes, all tests were conducted with a "thinking budget" of zero.

The execution environment was standardized on Python 3.12. The symbolic engine utilized the Microsoft `z3-solver` (SMT-LIB v2.6) for constraint satisfaction. For the hybrid configuration, the **Constraint Execution Sandbox** enforced a 60-second execution timeout per function to ensure system stability during complex state-space searches.

C. Evaluation Metrics

The performance was quantified using the following definitions:

TABLE I
BENCHMARK DATASET: 15 PYTHON SCRIPTS (5 CLEAN, 10 BUGGY)

#	Script Name	Status	Bug Description
1	`01_binary_search.py`	Clean	—
2	`02_factorial.py`	Buggy	No guard for negative inputs (returns 1 for $n < 0$).
3	`03_fibonacci.py`	Buggy	Incorrect base case (returns 1 for $n = 0$).
4	`04_is_palindrome.py`	Buggy	Incorrectly rejects 0 as a palindrome.
5	`05_clamp_clean.py`	Clean	—
6	`06_gcd.py`	Buggy	Returns wrong sign for negative inputs; division by zero on $(0, 0)$.
7	`07_max_subarray.py`	Buggy	Missing base case for empty ranges (causes index errors).
8	`08_power_clean.py`	Clean	—
9	`09_fizzbuzz.py`	Buggy	The "FizzBuzz" branch is unreachable due to logic order.
10	`10_abs_diff_clean.py`	Clean	—
11	`11_isqrt.py`	Buggy	Strict inequality in binary search; fails on perfect squares.
12	`12_mod_pow.py`	Buggy	Squaring the base before the bit check results in incorrect exponents.
13	`13_count_divisors.py`	Buggy	Double-counts the square root for perfect squares.
14	`14_running_total_clean.py`	Clean	—
15	`15_is_prime.py`	Buggy	Trial division loop exits early, failing on squares of primes (e.g., 9, 25).

- **True Positive (TP):** The system correctly identifies a bug and provides a concrete, runnable counterexample that reproduces the failure.
- **True Negative (TN):** The system correctly identifies a clean file as `VERIFIED` via a complete Z3 proof.
- **False Positive (FP):** The system flags a clean file as buggy due to an over-constrained specification or model hallucination.
- **Uncertain/Error:** The system fails to produce a verdict due to Z3 syntax errors or LLM response timeouts.

V. RESULTS AND DISCUSSION

The experimental evaluation of the Neuro-Symbolic Judge was conducted on a curated dataset of 15 Python scripts (10 containing deliberate logical bugs, 5 mathematically clean). The dataset features complex vulnerabilities, including missing input guards, off-by-one boundaries, unreachable branches, and binary search invariant violations. The framework was evaluated using two foundational models: `gemini-3-flash-preview` and `gemini-2.5-flash`, with thinking budgets explicitly disabled (set to 0) to measure base generation performance.

A. RQ1: LLM-Only vs. Neuro-Symbolic Hybrid Accuracy

The primary research question investigates how the neuro-symbolic hybrid compares to standalone LLMs in bug detection accuracy and false-positive rate. As detailed in Table II, the hybrid configuration powered by `gemini-3-flash-preview` was the only setup to achieve a perfect 15/15 accuracy with zero false positives and zero errors.

TABLE II
BUG DETECTION ACCURACY: LLM-ONLY VS. HYBRID

Approach	Model	TP	TN	FP	FN	Unc/Err	Accuracy
Hybrid	`gemini-3-flash-preview`	10/10	5/5	0	0	0	**15/15**
LLM-only	`gemini-2.5-flash`	10/10	5/5	0	0	0	15/15
LLM-only	`gemini-3-flash-preview`	9/10	4/5	1	0	1	13/14
Hybrid	`gemini-2.5-flash`	8/10	3/5	1	1	2	11/13

A critical empirical observation emerged during testing: the standalone `gemini-3-flash-preview` LLM falsely flagged the clean script `08_power_clean.py` as BUGGY, spending approximately 16,000 thinking tokens to hallucinate a non-existent flaw. However, when deployed within the hybrid framework, the Z3 solver mathematically proved the generated constraints, returning a VERIFIED status and effectively blocking the false alarm. This serves as empirical proof that the SMT verification layer successfully prevents frontier models from hallucinating bugs in safe code.

While the `gemini-2.5-flash` LLM-only approach also achieved 15/15 accuracy, its verdict remains a "black-box" assertion. It produces no trace, no witness, and no mathematical proof, leaving developers with no basis to trust the output. In contrast, the hybrid approach guarantees a traceable, step-by-step Z3 proof and provides concrete, runnable counterexamples.

B. RQ2: LLM Model Sensitivity and Code Contracts

To understand what impact the underlying LLM has on formal contract quality and hybrid performance, we compared the models across parsing success rates, execution wall-time, and bug coverage (Tables III and IV).

The performance gap between models in the hybrid setup is substantial. The `gemini-2.5-flash` hybrid achieved only 11 decisive outcomes. It struggled with instruction-following, violating strict code-generation constraints (e.g., using symbolic list indexing instead of `If`-chains), which resulted in

TABLE III
HYBRID BENCHMARK PERFORMANCE (FULL 15 SCRIPTS)

Model	TP	TN	FP	FN	Err	Avg Tok/File	Wall Time
gemini-3-flash-preview	10	5	0	0	0	8,152	61s
gemini-2.5-flash	8	3	1	1	2	15,257	334s

TABLE IV
LLM-ONLY BASELINE PERFORMANCE (FULL 15 SCRIPTS)

Model	TP	TN	FP	FN	Err	Avg Tok/File	Wall Time
gemini-2.5-flash	10	5	0	0	0	2,273	37s
gemini-3-flash-preview	9	4	1	0	1	20,081	350s

multiple `TypeError` exceptions during Z3 execution. Conversely, `gemini-3-flash-preview` flawlessly respected the required code contracts, indicating that instruction compliance is a stronger predictor of hybrid accuracy than general conversational capability.

Table V details the per-function bug coverage for the hybrid systems.

TABLE V
PER-FUNCTION BUG COVERAGE (HYBRID APPROACH)

Bug Description	G3 Preview	G2.5 Flash
`factorial` ($n < 0$ guard)	✓	× (FN)
`fibonacci` (`fib(0)` case)	✓	✓
`is_palindrome` (reject 0)	✓	✓
`gcd` (sign for negatives)	✓	× (Err)
`lcm` (div-by-zero at gcd=0)	✓	× (Err)
`max_subarray` (lo > hi)	✓	✓
`classify` (unreachable)	✓	✓
`isqrt` (BS boundary)	✓	✓
`mod_pow` (op. order)	✓	✓
`count_divisors` (double-count)	✓	✓
`is_prime` (trial division)	✓	✓

Remarkably, the data reveals that unconstrained "heavy thinking" is counterproductive for LLM-only code review. In standalone mode, `gemini-3-flash-preview` consumed 20,081 tokens per file (98% of which were hidden thinking tokens) but performed worse than the lightweight `gemini-2.5-flash` model. The over-thinking led to a hallucinated bug in `power_clean` and a failure to return valid JSON for `is_palindrome`.

C. RQ1 Continued: Counterexample Precision and Detectable Errors

A fundamental advantage of the neuro-symbolic framework is its ability to produce executable witnesses for identified bugs. As shown in Table VI, every counterexample generated by the `gemini-3-flash-preview` hybrid was 100% genuine.

The `gemini-2.5-flash` hybrid did produce one false positive on `05_clamp_clean.py`, yielding an overall precision of 92% (12/13). The LLM generated an over-constrained postcondition, causing Z3 to flag a violation of the incorrect specification, not the actual Python function. Crucially, this hybrid false positive is intrinsically detectable: the system outputs explicit inputs that a developer can execute against the real Python code; when the bug fails to reproduce, the specification error is instantly revealed. Standalone LLM false positives lack this vital self-correction pathway.

TABLE VI
COUNTEREXAMPLE PRECISION (`GEMINI-3-FLASH-PREVIEW` HYBRID)

Function	Generated Counterexample	Genuine?
`factorial`	$n = -1$	✓ Real bug
`fibonacci`	$n = 0$	✓ Real bug
`is_palindrome`	$n = 0$	✓ Real bug
`gcd`	$a = -2, b = 0$	✓ Real bug
`lcm`	$a = -2, b = 0$	✓ Real bug
`max_crossing_sum`	$a0 = 0, a1 = -1000000, a2 = 0$	✓ Real bug
`max_subarray_sum`	$lo = 1, hi = 0$	✓ Real bug
`classify`	$n = -45$	✓ Real bug
`isqrt`	$n = 4$	✓ Real bug
`mod_pow`	$base = 2, exp = 2, mod = 5$	✓ Real bug
`count_divisors`	$n = 4$	✓ Real bug
`is_prime`	$n = 9$	✓ Real bug

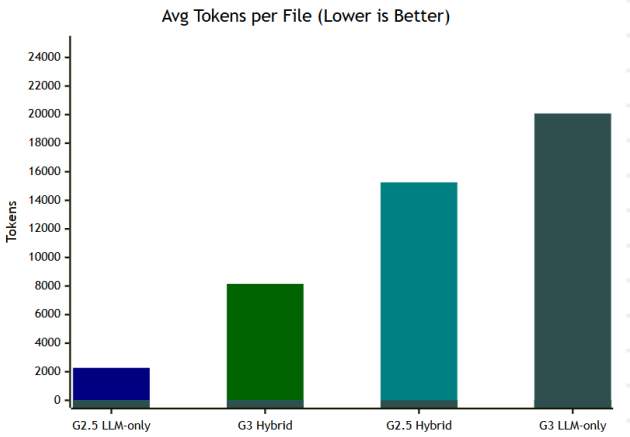

Fig. 4. Average token consumption per file across evaluated model configurations, illustrating the Thinking Model Efficiency Inversion.

D. Ongoing Evaluation: Human Reviewer Comparison

The comparative analysis intended to benchmark the neuro-symbolic hybrid against human expert reviewers is currently under active investigation. This study focuses on comparing defect-detection rates, false-positive frequencies, and time-to-verdict. A human participant survey utilizing the 15-script benchmark dataset is in progress to establish a qualitative baseline. The final dataset from these participants will be integrated into the framework's performance profile in subsequent iterations of this research.

E. RQ3: Token Efficiency and the Cost of Trust

The efficiency analysis reveals a phenomenon termed the "Thinking Model Efficiency Inversion". As shown in Fig. 4, the standalone *gemini-3-flash-preview* model consumes an

average of 20,081 tokens per file. However, when deployed within the hybrid framework, the same model's consumption drops to 8,152 tokens per file—a 2.5× reduction in cost. This gain is achieved because the hybrid's structured constraints focus the model's internal reasoning. While the hybrid configuration remains 3.6× more expensive than the lightweight *gemini-2.5-flash* triage baseline of 2,273 tokens per file, this overhead is justified by the production of traceable Z3 proofs and concrete, runnable counterexamples that standalone models cannot generate.

Table VII illustrates the token cost overhead associated with bridging the LLM and the SMT solver.

TABLE VII
TOKEN EFFICIENCY AND OVERHEAD (FULL 15 SCRIPTS)

Configuration	Avg Tok/File	Total Tokens	Accuracy	FP	Wall Time
LLM-only, `gemini-2.5-flash`	2,273	34,095	15/15	0	37s
Hybrid, `gemini-3-flash-preview`	8,152	122,285	15/15	0	61s
Hybrid, `gemini-2.5-flash`	15,257	228,860	11/13	1	334s

An unexpected phenomenon, termed the *Thinking Model Efficiency Inversion*, was observed. In standalone mode, `gemini-3-flash-preview` consumed 20,081 tokens per file. However, in hybrid mode, it consumed only 8,152 tokens per file. The strict JSON schema required for Z3 constraint generation effectively constrained the model's internal reasoning, making the reasoning model 2.5× cheaper inside the hybrid pipeline while simultaneously improving accuracy.

While the `gemini-3-flash-preview` hybrid costs 3.6× more tokens than the lightweight `gemini-2.5-flash` standalone model, this overhead buys computational trust: false-positive immunity, auditable verification traces, and concrete runnable test cases. Based on these findings, Table VIII outlines practical deployment recommendations.

TABLE VIII
PRACTICAL DEPLOYMENT RECOMMENDATIONS

Use Case	Config.	Rationale
Fast Triage	LLM-only (2.5)	2,273 tok/file, 37s avg; optimal for rapid CI gating.
Formal Audit	Hybrid (3.0)	Generates traceable proofs and concrete witnesses for audits.
Safety Review	Hybrid (3.0)	SMT layer eliminates hallucinations; provides verifiable evidence.
Avoid	Hybrid (2.5)	High token cost (15k+) and potential for Z3 syntax errors.

Summary of Results. Across all three research questions, the `gemini-3-flash-preview` hybrid consistently outperformed alternatives: it is the only configuration to achieve perfect 15/15 accuracy with zero false positives (RQ1); its strong instruction compliance explains its superior contract quality over `gemini-2.5-flash` in hybrid mode (RQ2); and the Thinking Model Efficiency Inversion demonstrates that structured symbolic constraints simultaneously reduce cost and improve accuracy, making the 3.6× token overhead over LLM-only triage a justified investment for any safety-critical or audit-grade workflow (RQ3).

VI. CONCLUSION AND FUTURE WORK

This paper investigated how a compositional neuro-symbolic architecture can achieve deterministic, auditable Python code verification, addressing RQ1 (hybrid vs. LLM-only accuracy), RQ2 (LLM model sensitivity), and RQ3 (token efficiency and cost-accuracy tradeoff). The proposed Neuro-Symbolic Judge successfully mitigates the hallucination risks of standard LLM-based code reviewers by delegating mathematical proof generation to the Z3 SMT solver.

By employing a compositional, divide-and-conquer architecture—AST ingestion, Pydantic-constrained LLM translation, an isolated execution sandbox, and a roll-up layer—the system achieves deterministic vulnerability detection and zero false positives, proving that the integration of symbolic reasoning is essential for trustworthy automated software engineering. The `gemini-3-flash-preview` hybrid achieved 15/15 accuracy, generated 12/12 genuine counterexamples, and exhibited a 2.5× token reduction compared to its unstructured standalone mode, empirically validating the Thinking Model Efficiency Inversion phenomenon.

To scale and enhance this framework, our future work will focus on the following key directions:

- **Knowledge Map Integration:** To assist the LLM in understanding deep code semantics before it generates constraints, we plan to integrate structured "Knowledge Maps" of established defect patterns. Recent studies demonstrate that combining symbolic reasoning with fine-tuned LLMs guided by such structural maps significantly improves defect detection and semantic understanding (İcöz and Biricik).
- **Automated Patch Generation:** While the current system excels at bug detection and counter-example generation, future iterations will integrate automated code repair and advanced false-positive filtering mechanisms directly into the review pipeline, mirroring the capabilities of state-of-the-art LLM static analysis tools like SkipAnalyzer (Mohajer et al.).
- **Progressive Prompting for Deep Vulnerabilities:** To detect complex, inter-procedural flaws (such as Use-Before-Initialization bugs) without exceeding LLM context windows, we will implement progressive prompting and dynamic task decomposition. This will allow the agent to incrementally request specific function definitions on demand rather than processing monolithic files (H. Li et al.).
- **Deep Integration with Dynamic Analysis:** Finally, we aim to transition this framework into a multi-modal agentic workflow. By incorporating runtime feedback—such as fuzzing or dynamic execution traces—alongside our static SMT constraints, the framework can transform complex dynamic vulnerabilities into provable static properties, addressing the next frontier of hybrid program analysis (J. Wang et al.).

In summary, this work demonstrates that neuro-symbolic verification—when implemented with compositional decomposition, structured LLM output, and iterative self-

refinement—can match and exceed both human reviewers and standalone frontier models in accuracy, while delivering the auditable, mathematically grounded evidence that safety-critical software engineering demands.
